Abstract

We report on a high precision Montecarlo test of the three dimensional Ising gauge model at finite temperature. The string tension σ is extracted from the expectation values of correlations of Polyakov lines. Agreement with the string tension extracted from Wilson loops is found only if the quantum fluctuations of the flux tube are properly taken into account. The central charge of the underlying conformal field theory is $c = 1$.

1. Introduction

In the last years lot of efforts have been devoted to extract interquark potential from lattice gauge theories (LGT's) looking at the expectation values of Wilson loops or (correlations of) Polyakov lines in Montecarlo simulations. Besides the important issue of obtaining reliable values of physical observables like the string tension, these simulations also allow to study the physical nature of the potential. In particular, more and more convincing evidences have been reported in last years of the so called "string picture" of the interquark potential: quark and antiquark linked together by a thin fluctuating flux tube [1].

Roughly speaking, there are two independent ways to check this picture.

The first one is to try to observe directly the flux tube, for instance as a stable semiclassical configuration, surviving cooling [2] or looking at the space distribution of colour flux [3].

The second one, followed in this paper, is to look at the finite size effects due to quantum string fluctuations, which, in finite geometries, give significative, measurable contributions to the interquark potential. This second approach traces back to the work of Lüscher, Symanzik and Weisz [4] and has interesting connections with the conformal field theory (CFT) approach of two-dimensional models developed in the last years[5].

This approach has particularly relevant consequences if one studies Polyakov lines in LGT's at finite temperature, because in this case the finite size corrections (which we shall call from now on "string contributions") have a very specific behaviour, due to the choice of boundary conditions.

The existence of the string contributions and their explicit asymptotic form can be deduced from a purely theoretical point of view as consistency conditions of non-perturbative descriptions of the infrared behaviour of gauge theories.

These corrections seem necessary to fit the data of Montecarlo simulations [6, 7]. In order to give further evidence of this fact, we shall compare our theoretical predictions with a new set of high precision data on the Ising gauge model at finite (but low) temperature. In particular, taking into account the non trivial topology of the finite temperature model, we shall be able to estimate the conformal anomaly c of the CFT which describes

the long distance behaviour of the transverse displacements of the string : it turns out to agree with the value $c = 1$ suggested by the naive bosonic string picture.

This paper is organized as follows: after a general introduction to the finite temperature gauge models (sect.2), in sect.3 we motivate our approach and show the general features of contributions coming from the quantum fluctuations of the flux tube. Section 4 is then devoted to the explicit description of the finite temperature string corrections . In sect.5 we describe our simulation and discuss the results.

2. Finite temperature gauge theories: general setting and notations

The partition function of a gauge theory with gauge group G regularized on a lattice is

$$Z = \int \prod dU_l(\vec{x}, t) \exp\{-\beta \sum_p \text{Re Tr}(1 - U_p)\} \quad , \quad (1)$$

where $U_l(\vec{x}, t) \in G$ is the link variable of position $(\vec{x}, t)$ and direction $l \in \{x_1, \dots, x_d, t\}$ and U_p is the product of the links around the plaquette p .

Let us call N_t (N_s) the lattice size in the time (space) direction (we assume for simplicity N_s to be the same for all the space directions). A $(N_s)^d N_t$ lattice can then be interpreted as representing a system with a finite volume $V = (N_s a)^d$ and a finite temperature $T = 1/L = 1/N_t a$ where a is the lattice spacing. Lattice simulations with non-zero temperature are obtained imposing periodic boundary conditions in the time direction.

The order parameter of the finite temperature deconfinement transition is the Polyakov line, *i.e.* the trace of the ordered product of all time links with the same space coordinates and it is closed owing to the periodic boundary conditions in the time direction:

$$P(\vec{x}) = \text{Tr} \prod_{z=1}^{N_t} U_t(\vec{x}, z) \quad . \quad (2)$$

The vacuum expectation value of the Polyakov line is zero in the confining phase and acquires a non-zero expectation value in the deconfined phase. The value $\beta_c(T)$ of this deconfinement transition is a function of the temperature, and defines a new physical observable T_c .

The interquark potential can be extracted by looking at the correlations of Polyakov lines in the confined phase. The correlation of two lines $P(x)$ at a distance R and at a temperature $T = 1/L = 1/N_t a$ is given by

$$\langle P(x)P^\dagger(x+R) \rangle = e^{-F(R,L)} \quad , \quad (3)$$

where the free energy $F(R, L)$ is expected to be described, as a first approximation, by the so called “area law”:

$$F(R, L) \sim F(R, L)_{cl} = \sigma LR + c(L) \quad , \quad (4)$$

where $c(L)$ is a constant depending only on L .

The observable (3) is similar to the expectation value of an ordinary Wilson loop except for the boundary conditions, which are in this case fixed in the space directions and periodic in the time direction. The resulting geometry is that of a cylinder, which is topologically different from the rectangular geometry of the Wilson loop.

3. The role of the quantum fluctuations of the flux tube

According to an old, long standing conjecture [1], the area term is only the dominant (classical) contribution of the effective string which should describe the infrared behaviour of the gauge theory (this explains the subscript “cl” in eq.(4)). The effective, non critical strings are (as it is well known) intractable in more than one dimension. Mainly as a consequence of that, it has become a common habit in LGT’s to ignore the quantum corrections implied by the effective string hypothesis, only retaining the classical (area) contribution in fitting the data of Montecarlo simulations. We shall see below the range of validity and the consequences of this “zero order approximation”.

A way out of this problem is to realize that, for large quark separations, we do not need to describe the full complexity of the effective string theory, but only the degrees of freedom which survive at large distance.

Indeed the notorious troubles of the non critical strings (the breaking of the Lorentz invariance or the coupling to the Liouville modes) asymptotically disappear at large distances [8]. In such a region the transverse degrees of freedom of the string are described by the free, massless bosonic fields of an ordinary two-dimensional CFT.

The corresponding partition function $Z(R, L)$ will be the first order quantum contribution of the effective string to the Polyakov line correlation (or Wilson loop) expectation value. Consequently, taking into account the corresponding free energy $F(R, L)_q = -\log Z(R, L)$, we modify eq.(4) as follows:

$$F(R, L) \sim F(R, L)_{cl} + F(R, L)_q = \sigma LR + c(L) - \log Z(R, L) \quad . \quad (5)$$

Due to the recent progress in CFT's [5] we can study the behaviour of $F(R, L)_q$ as a function of R and L in a general way. Indeed any two dimensional CFT is completely described once the conformal anomaly c , the operator content h_i and the operator product algebra (or the fusion algebra which equivalently encodes all the fusing properties of the CFT) are given; then it is easy to show that $F(R, L)_q$ only depends on the adimensional ratio $z = 2R/L$. It is possible to give asymptotic expressions for $F(R, L)_q$ in the $z \gg 1$ and $z \ll 1$ regimes:

$z \gg 1$ [9]

$$F(R, L)_q \simeq -(d-2) \tilde{c} \frac{\pi R}{6L} \quad , \quad (6)$$

where d is the space time dimensions of the gauge theory and $\tilde{c} = c - 24h_{min}$ is the effective conformal anomaly [10]; h_{min} is the lowest conformal weight of the physical states propagating along the cylinder. In the case of unitary CFT's $h_{min} = 0$ (unless special boundary conditions are chosen) and $\tilde{c}$ coincides with the conformal anomaly c ;

$z \ll 1$ [11]

$$F(R, L)_q \simeq -(d-2) \hat{c} \frac{\pi L}{24R} \quad , \quad (7)$$

where $\hat{c} = c - 24h_{\alpha, \beta}$ and $h_{\alpha, \beta}$ is the lowest conformal weight compatible with the boundary conditions α and β at the two open ends of the cylinder.

If the CFT is exactly solvable, namely if the whole operator content is known, one can explicitly write the free energy for all values of z , which will smoothly interpolate between the two asymptotic behaviours.

In the Wilson loop case, since all the boundaries of the loop are open (rectangular geometry), we only have the behaviour given by eq.(7), with a partition function $F(R, L)_q$ symmetric under the exchange $R \leftrightarrow L$.

An important role in this construction is played by the modular transformations. All the partition functions can be written as power expansions

in $q = \exp(2\pi i\tau)$, with $\tau = iz$ for Polyakov line correlations or $\tau = i\frac{R}{L}$ for Wilson loops. Modular transformations allow to extend these expansions in the whole τ plane. In particular we will be interested, in the following, in the $\tau \rightarrow -1/\tau$ transformation.

In the Wilson case, this transformation is a symmetry, because it exchanges R and L . We can use this symmetry by choosing for instance $L \geq R$, and $\tau = iL/R$. Here L plays the role of time and the interquark potential $V(R)$ we want to extract from the data is defined in the limit: $V(R) = \lim_{L \rightarrow \infty} F(R, L)/L$.

In the Polyakov case the situation is different: L and R have a different meaning and the modular transformation $\tau \rightarrow -1/\tau$ allows us to move from the region in which $2R > L$ to that in which $2R < L$. What is new is that, due to the modular transformation, in these two regions the string corrections have, as we have seen above, different functional forms. While in the region in which $2R < L$ the dominant contribution is, like in the Wilson case, of the type $1/R$, in the region in which $2R > L$ the dominant contribution is proportional to R , and acts as a finite size correction of the string tension. This behaviour will play a major role in the following.

Let us now look at the other side of the problem: the data coming from computer simulation. Indeed, in the last years, as a consequence of the improvement in precision and size of the Montecarlo simulations of LGT's, serious problems arose in the interpretation of data. These problems can be summarized into three items:

- a) scaling deviations,
- b) disagreement between data and the “area, perimeter and constant” law,
- c) disagreement between Wilson loop and Polyakov line correlation estimates of the string tension.

Let us briefly discuss these items.

- a) It is well known that the most safe way one has to separate physically meaningful quantities from lattice artifacts is to test their correct scaling behaviour near the continuum limit, and this is the only ultimate check of the whole Montecarlo procedure. Indeed, one of the earliest success of LGT's was the identification of such a scaling behaviour in the string tension [12].

However the improvement in the precision and size of lattice simula-

tions led to the observation of significant deviations from asymptotic scaling [13] of the string tension extracted from Wilson loops. In [6, 7] we have shown that taking into account string corrections a good scaling behaviour could be obtained for the string tension extracted from Wilson loops both in 4D $SU(2)$ and $SU(3)$ models [6] and in 3D Z_2 and Z_5 models [7].

We shall show in this paper a similar scaling behaviour for the string tension σ extracted from Polyakov line correlations at finite temperature. What is peculiar of the Polyakov case is that the string corrections for $z > 1$ act simply as a renormalization of σ (see eq.(6)); as a consequence, in this region the scaling behaviour of σ can be obtained even if one neglects string corrections .

Owing to the fact that in the actual simulations the size L is always rather small, it is enough to cut off few short range (i.e. small R) data to reach $z > 1$ and hence scaling.

This probably explains why in the last years Polyakov line correlations have been so popular in estimating the string tension and have almost substituted Wilson loops.

- b) The seeming absence of scaling of the string tension extracted from the Wilson loops or Polyakov line correlations at short distance is mainly due to a sizable violation of the expected area law of the Montecarlo data. As a matter of fact, if one tries to fit also the short range data with the area law, the resulting χ^2 is unacceptably high. Moreover, setting a lower cut-off on the fitted data, a definite systematic trend can be seen in the resulting string tension, which decreases as the lower bound increases (see fig.1). Let us stress that this behaviour is impressively universal: it can be seen in the string tension extracted both from Wilson loops or Polyakov line correlations, either in non abelian $SU(2)$ and $SU(3)$ gauge theories in four dimensions [6], or in the Z_2 model in three dimensions [7], . Most probably, this systematic trend is the main reason of the fact that, as simulations were performed on lattices of larger and larger size, and bigger Wilson loops could be reached, the published values of, say, the pure QCD string tension became smaller: from the $\frac{\sqrt{\sigma}}{\Lambda} \sim 140$ of ref. [12] in 1980 to the $\frac{\sqrt{\sigma}}{\Lambda} \sim 80$ estimate of ref.s [14, 6, 15, 16].

If one goes on in eliminating short range data, acceptable confidence levels are eventually reached when all the data below a suitable thresh-

old R_σ are ignored.

Unfortunately this agreement with the area law is only apparent; indeed if we increase R_σ further, we still observe a decreasing string tension, a trend which is hidden by the error bars (linearly growing with the distance) thus allowing apparently good χ^2 (see fig.1). However the values of σ extracted at these values of R_σ do not scale as a universal function of β as they should do in the asymptotic scaling region.

Notice that this behaviour of σ as a function of R_σ is not a lattice artifact, since it scales, as we shall see below. In particular, we shall account for this behaviour by considering the contributions of the quantum fluctuations of the string.

Let us conclude this item with a remark on the physical scales involved in these quantum fluctuations. In principle, one could ignore all these complications simply by looking at very large Wilson loops. This corresponds, in the continuum limit, to study quark-antiquark pairs with large separations. Taking as an example SU(3) in 4D and physical unities, we can ignore string corrections for distances greater than ~ 1 fm., but they are definitely relevant at distances (~ 0.2 fm.) typical of heavy quarkonia ($c\bar{c}$, $b\bar{b}$).

- c) In this paper we study the Ising gauge model at finite, but low, temperature, where all the effects of the deconfinement transition can be neglected¹. In this region the string tension measured with Wilson loops should be the same of the zero temperature case. In fact, extracting σ from Wilson loops orthogonal to the time direction, we found that its value, (compared with the zero temperature results of ref. [7]²) is unaffected, within statistical errors, by the compactification of the time direction. On the contrary, if we extract the string tension from Polyakov line correlations, a different value is obtained, unless

¹These effects of extreme interest for the effective string picture, since the quantum string fluctuations are more relevant near the deconfinement point. However one should take into account higher order contributions. We have chosen to avoid these complications in order to make more definite the comparison between Montecarlo data and our predictions.

²Actually, owing to the finite size (32^3) of the lattice, also the data of ref. [7] should be considered, roughly speaking, as non-zero temperature estimates of the string tension. To be precise in [7] the range of temperatures was from 0.35Λ at $\beta = 0.740$ to 0.61Λ at $\beta = 0.7525$, where the scale Λ is defined in eq.(19).

string corrections are taken into account. Indeed this is a well known phenomenon: the string tension extracted from Polyakov line correlations is systematically lower than that extracted from Wilson loops (see for instance [17]). The difference between the two observables is only in the boundary conditions: these do not affect the area term (hence we expect the same value of σ), but they change the string corrections. As we noticed above, in the Polyakov case, for large values of the interquark distance we must subtract to σ , the term $\frac{\tilde{c}(d-2)\pi}{6L^2}$, which explains the disagreement between the measured values [17]. Our analysis on the 3D Ising gauge model agrees with a value $\tilde{c} = 1$ for the conformal anomaly.

The simplest possible choice for the effective string is given by the Nambu-Goto action, which is obtained by identifying the flux tube with the string. The quantum fluctuations of this string can be described, for large quark separations, by a gaussian model with $d - 2$ free bosonic fields that we shall call in the following the free bosonic string. This is the simplest possible 2D CFT and can be solved exactly.

The functional integration over the $(d - 2)$ bosonic fields can be done using the ζ function regularization, and strongly depends on the topology of the world-sheet [18, 19, 20, 21]. One finds $\tilde{c} = \hat{c} = c = d - 2$ for the effective conformal anomalies defined in eq.s(6,7). Taking into account this contribution, we get a definite improvement in the description of the data and the above mentioned discrepancies partially disappear. In particular the problem of point c) is completely solved as we shall show in the following.

Notice that this improvement is quite general and works for gauge theories both in three and four dimensions, both with discrete and with continuous groups.

The free bosonic string can be considered as a sort of mean field approximation of the proper effective string description and as such, for instance, predicts the same (mean field) critical index $\nu = 1/2$ near the deconfinement transition for all gauge theories (see ref. [22] for a discussion of this point).

There are three features of the bosonic string which explain in which sense it is an approximation of the physical flux tube:

- i) The bosonic string can freely self-overlap, a feature which does not agree with our intuition on gauge theory coming both from strong coupling expansions (in a Z_2 gauge theory, each plaquette must appear at

most once in any strong coupling diagram) and from semi-classical descriptions of the flux tube.

- ii) The bosonic string has zero thickness, while the flux tube has a nonzero, measurable thickness [3].
- iii) The bosonic string predicts, for the short distance behaviour of σ [23, 24]:

$$\sigma(R) = \sigma(\infty) \sqrt{1 - \left(\frac{R_c}{R}\right)^2} \quad . \quad (8)$$

The term that we can obtain using CFT's (see sect.4) is only the first order one in the $1/R$ expansion of eq.(8). Consequently we expect that it underestimates the true contribution and that, once it has been subtracted, the decreasing behaviour of $\sigma(R)$ should be weaker, but still present. This is exactly the opposite of what we observe. Both in the case of Wilson loops (see fig.4 of ref.[7]) and in the case of Polyakov line correlations (see fig.1 of the present paper), once bosonic string corrections are taken into account, $\sigma(R)$ has the wrong shape.

The free bosonic string is a good description of the effective string at large distances and low temperatures: it works for values of R and of the temperature such that the finite thickness of the flux tube can be ignored, and the self-overlapping probability is negligible.

A simple way to take into account the presence of a new scale (namely the finite thickness of the flux tube) in the problem, is to compactify into a circle the bosons describing the transverse displacements. There are several ways to look at this compactification: one may either think that the string is not any more identified with the flux tube but wraps around it [25], or notice that a compactified boson can be fermionized and hence one can look at the model as a fermionic string description [6, 7, 25] or, using the connection between critical $O(n)$ models and compactified bosons, one can discuss the string corrections in term of self-avoiding walks [26].

All these approaches capture some of the physical content of the model, and can give some semiclassical and intuitive justifications, but let us stress again that the ultimate reason for introducing a compactification radius is only to set a new scale in the model. This scale does not represent a new degree of freedom, since general consistency requirements fix the compact-

ification radius to be exactly $1/4$ in conventional units [25] and select the operator content of the underlying CFT [25, 26].

The compactification on a circle of rational radius leads to a simpler description of the CFT in terms of Dirac fermions with a finite number of spin structures [6, 7, 25]. In the following we shall call this model “fermionic string”. As expected, the large distance behaviour of the fermionic string is the same of that of the free bosonic string. In particular, one can show that again $\tilde{c} = c = 1$, hence both strings predict the same gap between Polyakov and Wilson estimates of σ . The difference between the two models becomes sensible when short distance data (of the order of the flux tube thickness) are taken into account: in fact it can be shown that now $\hat{c} = (d - 2)/4$. In this region the area law corrected with fermionic string contributions gives definitely better χ^2 ’s, and reliable scaling values of the string tension can be extracted (see for instance refs [6, 7]). Finally, a further signature of the better behaviour of the fermionic corrections with respect to the bosonic ones is given by the shape of the string corrected function $\sigma(R)$ which, as expected, is still a weakly decreasing function of R (see fig.1 for the Polyakov line correlations and fig.4 of ref. [7] for Wilson loops).

In this paper we shall confirm this picture also in the finite temperature case.

4. String corrections in the finite temperature geometry

The case of the free bosonic string was discussed in refs [18, 19] and with a different approach in ref.[20] (while the calculation for the rectangular geometry can be found in [21]). The result is, for $d = 3$,

$$F_b(R, L) = \log(\eta(\tau)) \quad ; \quad -i\tau = \frac{L}{2R} \quad , \quad (9)$$

where η denotes the Dedekind eta function:

$$\eta(\tau) = q^{\frac{1}{24}} \prod_{n=1}^{\infty} (1 - q^n) \quad ; \quad q = e^{2\pi i\tau} \quad , \quad (10)$$

and R is the distance between the two Polyakov lines.

We list below for completeness the power expansions in the two asymptotic regions:

$$2R < L$$

$$F_b(R, L) = -\frac{\pi L}{24R} + \sum_{n=1}^{\infty} \log(1 - e^{-\pi n L/R}) \quad , \quad (11)$$

$$2R > L$$

$$F_b(R, L) = -\frac{\pi R}{6L} + \frac{1}{2} \log \frac{2R}{L} + \sum_{n=1}^{\infty} \log(1 - e^{-4\pi n R/L}) \quad . \quad (12)$$

Following the same line of reasoning, one can also obtain the string correction in the case in which the transverse degrees of freedom of the string are described by fermionic fields³. We shall list here, for completeness, the results for generic values of the compactification radius r , and then concentrate on the value $r = 1/4$.

The string is described by a Dirac spinor $\psi(\xi_1, \xi_2)$ ($0 \leq \xi_1 \leq R, 0 \leq \xi_2 \leq L$) with components $\psi_{\pm}(\xi_1, \xi_2) = \psi_{\pm}(\xi_1 \pm \xi_2)$, associated to the transverse dimension.

The value of the quantum correction depends on the boundary conditions of ψ on the two fixed edges of the cylinder (the Polyakov lines). Defining a boundary phase $\alpha = \frac{1}{N}$ through the relation

$$\psi_{\pm}(\xi_1 + 2R, \xi_2) = e^{\pm 2\pi i/N} \psi_{\pm}(\xi_1, \xi_2) \quad , \quad (13)$$

one has

$$F_{f,N}(R, L) = -\log \sum_{m=0}^{N-1} \frac{\vartheta_{[1/N-1/2]}^{[m/N-1/2]}(0|\tau)}{\eta(\tau)}; \quad -i\tau = \frac{2R}{L} \quad , \quad (14)$$

where $\vartheta_{[\beta]}^{[\alpha]}(0|\tau)$ is the Jacobi Theta function with characteristic $[\beta]$. One can write explicitly $\vartheta_{[\beta]}^{[\alpha]}(0|\tau)$ in terms of an infinite product in analogy with eq.(10):

$$\frac{\vartheta_{[\beta]}^{[\alpha]}(0|\tau)}{\eta(\tau)} = q^{\frac{\alpha^2}{2} - \frac{1}{24}} \prod_{n=1}^{\infty} (1 + q^{n+\alpha-\frac{1}{2}} e^{2\pi i \beta}) (1 + q^{n-\alpha-\frac{1}{2}} e^{-2\pi i \beta}) \quad . \quad (15)$$

Given the above expressions the series expansions for $z < 1$ and $z > 1$ are, in the case of $N=4$:

³This was done for rectangular geometry (Wilson loops) in ref.s [6, 7] in the case of Majorana fields (Ising model) and for Dirac fermions (c=1 conformal field theory) with arbitrary boundary conditions.

$$2R < L$$

$$F_{f,4}(R, L) = -\frac{\pi L}{96R} - \log[4(1 + q + 2q^2 + \dots)] \quad (16)$$

$$\text{with } q = \exp(-\frac{\pi L}{R}) \quad ,$$

$$2R > L$$

$$F_{f,4}(R, L) = -\frac{\pi R}{6L} - \log(1 + \sqrt{2 + \sqrt{2}q^{1/32}} + \sqrt{2}q^{1/8} + \dots) \quad (17)$$

$$\text{with } q = \exp(-\frac{4\pi R}{L}) \quad .$$

Notice that while the bosonic and the fermionic strings have quite different behaviours in the region $2R < L$ due to the different operator content, they give *exactly the same dominant contribution* in the region $L < 2R$ since they have the same conformal anomaly $c = 1$ and both are unitary CFT's. In this regime the only relevant difference between the two strings is a subdominant contribution of the type $\log R$: this is present only if the boundary conditions of the transverse degrees of freedom are periodic (like in the case of the bosonic string) and is forbidden if they are non-trivial (like in the fermionic case).

The above listed contributions are, as a matter of fact, only the first order terms of the string corrections to the interquark potential. They are expected to be valid in a window far enough from the roughening transition so as to allow the string to fluctuate, but not too near to the deconfinement transition where the string delocalizes, and the higher order effects due to self-overlapping become important.

5. Comparison with Montecarlo data

In order to measure the conformal anomaly c we made extensive high statistics simulations of a $3D$ Ising lattice gauge theory, extracting Wilson loops and Polyakov line correlations in a wide range of values of the ratio R/L .

We used the standard action

$$S = -\beta \sum_p U_p \quad , \quad (18)$$

where U_p denotes the product of Z_2 variables associated to the links belonging to the plaquette p . This model is known to have a roughening

transition at $\beta_r = 0.4964$ and a zero temperature deconfinement transition at $\beta_c(N_t = \infty) = 0.7614$ [27] which is of second order. The corresponding critical index is $\nu \sim 0.63$ [28]. The scaling region of the finite temperature $T = 1/N_t a$ deconfinement transition starts approximatively at $N_t = 4$. Data obtained with the Montecarlo renormalization group approach [29] for $N_t = 4$ and $N_t = 8$ give $\beta_c(N_t = 4) = 0.7315(5)$ and $\beta_c(N_t = 8) = 0.7516(5)$ which correspond to the following value of the critical temperature T_c

$$T_c/\Lambda \equiv T_c a(\beta_c(\infty) - \beta_c(N_t))^{-\nu} = 2.3 \pm 0.1 \quad , \quad (19)$$

which is also in agreement with an independent prediction based on the N=2 supersymmetric behaviour of the critical point [30].

We made six Montecarlo simulations on lattices of sizes $(N_s)^2 N_t$ for the values of β and N_t described in tab.I . These values have been chosen in order to check both the scaling as a function of β and the temperature dependence of the physical observables. In fact the first three combinations: $(\beta = 0.739, N_t = 12)$, $(\beta = 0.742, N_t = 13)$, $(\beta = 0.746, N_t = 15)$, roughly correspond to the same physical temperature $T/\Lambda \sim 0.92$ (see tab.I), while the second set: $(\beta = 0.739, N_t = 13)$, $(\beta = 0.742, N_t = 14)$, $(\beta = 0.746, N_t = 16)$ corresponds to $T/\Lambda \sim 0.85$. These are the lowest temperatures that we could reach with our precision.

The consistency of our data with the zero temperature result tells us that they are low enough to be unaffected by the higher order corrections which appear near the deconfinement transition. The size in the space directions was fixed to be $N_s = 48$, and periodic boundary conditions were chosen also in these directions. A standard heat-bath algorithm was used to update links. We measured all the possible Polyakov line correlations, and in the two experiments, $(\beta = 0.739, N_t = 13)$ and $(\beta = 0.746, N_t = 15)$,⁴ we also measured Wilson loops (orthogonal to the time direction) of sizes (R, L) in the range $2 \leq R, L \leq 20$.

The major problem we had to face was the critical slowing down. We have already discussed this problem in ref. [7]. Comparing the present data with those of ref. [7], we can say that the problem is even more severe with finite temperature simulations. Moreover, Polyakov line correlations are in general more self-correlated than Wilson loops. We kept under control this problem separating the measure of two successive Wilson loops and Polyakov

⁴We have chosen the two extreme situations, both in β and in T .

line correlations with 64 sweeps. We also developed a code so as to scatter both in space and (Montecarlo) time the measured correlations, trying to optimize not only self-correlations but also cross-correlations. We think that this procedure could allow a significative improvement in precision for any LGT simulation. The typical run was composed by 200.000 sweeps of thermalization and 960.000 sweeps during which 15.000 measures of Polyakov line correlations and Wilson loops were taken.

The resulting expectation values were fitted first with the pure area law and then adding the fermionic string quantum contribution (eq.s(16,17)). This correction being fixed, we do not add new free parameters in the fitting procedure, hence the two fits (with and without quantum contribution) can be directly compared. In fitting the data we had also to take into account the periodicity of the lattice: the same correlation between two Polyakov lines could also be obtained following topologically non-trivial paths, winding around the compactified space directions. We made nonlinear fits summing over the nearest winding numbers⁵. So the fitting function was

$$\langle P(\vec{x})P(\vec{x} + \vec{R}) \rangle = \sum_{i,j=-1}^{i,j=1} e^{-F(R_{i,j}, N_t)} \quad , \quad (20)$$

with

$$R_{i,j} = \sqrt{(R_x + iN_s)^2 + (R_y + jN_s)^2} \quad , \quad (21)$$

R_x and R_y being the Euclidean components of the vector $\vec{R}$ and

$$F(R_{i,j}, N_t) = \sigma R_{i,j} N_t + cost + F_{f,4}(R_{i,j}, N_t) \quad . \quad (22)$$

Being N_t fixed, the constant term must be the same for all the correlations. Notice that this fit is definitely more constrained than the similar one for Wilson loops, since in this case we have only two free parameters, namely $cost$ and σ , instead of the three of the Wilson loop.

In fitting the data we used the expansions of $F_{f,4}$ up to the sixth order⁶ in q (eq.s(16,17)) both in the region $z < 1$ and in $z > 1$. The Wilson loops analysis was done as described in ref. [7].

⁵The same problem can be ignored with Wilson loops.

⁶As a matter of fact only the dominant term and the second order give significative contributions for generic values of z , higher orders become relevant only in the point $z = 1$ where they allow the smooth connection of the two asymptotic behaviours. Since this point turns out to be very important in our fits, we decided to keep higher orders anyway.

Before discussing our results let us make few general comments on the data:

1. A first feature of the Polyakov line correlations is their impressively good scaling behaviour (which is shown in fig.2) even before any cutting or fitting manipulation. The two sets of data which overlap in fig.2 are taken at different values of β and N_t tuned so as to give the same physical temperature. The tuning crucially involves the critical index $\nu = 0.63$ and tells us first, that we are in the scaling region and second, that, as expected, all the data are controlled only by the two physical scales T and σ .
2. As described in sect.3, we cannot expect to see any string effect in the R dependence of Polyakov line correlations at large distances ($z > 1$) (in this region the only signature of the string is in the T dependence of σ and it can be seen only by comparison with the Wilson loops, being the two values of T we explore are too near to give measurable effects). On the contrary string effects should be visible for $z < 1$ as deviations from the linear rising behaviour of the potential. This is clearly visible in fig.3. In this figure the potential $V(R)$, defined as

$$V(R) = -\frac{1}{N_t} \log \langle P(x) P^\dagger(x+R) \rangle \quad , \quad (23)$$

is plotted against the interquark distance R . The linear rising behaviour is clearly visible for $z > 1$ (in the example $z = 1$ corresponds to $R = 7.5$), and similarly evident is the smooth onset of the $1/R$ correction for $z < 1$.

Let us now concentrate on the quantitative tests. We made several fits, cutting off short range data, as described in sect.2 and for the Wilson loops we cut off short range data following the procedure of ref. [7]. The result of these fits is a set of values of the string tension $\sigma(\beta, N_t, z_{min})$ (in the case of Wilson loops z_{min} is substituted by R_{min}), which depend on β , on the temperature $T = 1/N_t a$ and on the threshold z_{min} (R_{min}). Wilson loops data are listed in tab.II together with two sets of data taken from ref.[7] for comparison. The Polyakov line correlation data are listed in tab.III. The errors on σ have been estimated with an ordinary jackknife procedure, and the data are presented taking into account their scaling behaviour in β :

$$k = \frac{\sigma}{(\beta_c - \beta)^{2\nu}} \quad . \quad (24)$$

Let us examine first the data coming from Wilson loops. We can see from tab.II that:

If we add the fermionic correction, all data agree among them: for all the sets, acceptable confidence levels are obtained already from $R_{min} = 3$, and, starting from the same threshold, scaling is fulfilled.

On the contrary, if we neglect quantum corrections, acceptable confidence levels with the area law are reached only at $R_{min} = 5$, and, what is more important, *scaling is never reached*.

It is quite interesting to see that the data show no dependence at all from the finite temperature. This is particularly impressive for the results obtained without the string corrections: the differences between various β 's due to the scaling violations are much bigger than the difference between zero temperature and finite low temperature data for nearby values of β : the data at $(\beta = 0.739, T/\Lambda = 0.84)$ are much more similar to those at $(\beta = 0.740, T = 0)$ than to those at $(\beta = 0.746, T/\Lambda = 0.92)$, and similarly for the other pair $(\beta = 0.746, T/\Lambda = 0.92)$ and $(\beta = 0.745, T = 0)$.

The values of σ obtained with the string corrections still show a decreasing trend in the region $R_{min} > 3$. This behaviour was already noticed and discussed in ref. [7]: it can be ascribed to higher order contributions of the string and can be successfully fitted with a root law [7]. The important point is that this trend (as a difference with the no-string case) becomes asymptotic already in the region $R_{min} = 5, 6$ which we can reach with our measures. Since the new data are in agreement with those at $T = 0$, we can borrow the result of ref. [7] and give

$$k_w \equiv \frac{\sigma_{wilson}}{(\beta_c - \beta)^{2\nu}} = 3.65(9) \quad (25)$$

as a final value for the string tension extracted from Wilson loops.

Analyzing now the data coming from Polyakov line correlations (tab.III) we can see that:

In general, for the string-corrected fits, acceptable confidence levels are obtained for $z \geq z_{min} = 0.6$, while using the pure area law one finds acceptable CL only for $z \geq z_{min} = 0.8$.

The fits to the scaling law show the same thresholds and give definitely good confidence levels for $z \geq z_{min} = 1.2$, a region in which the string correction only acts as a renormalization of σ (see eq.(17)). However the fact that the fermionic string describes better the data can be still stressed observing that, after $z = 1.0$, the string-corrected data give a stable σ , while those obtained with the pure area law keep decreasing.

Taking as final answer for the string tension the value (and error) extracted at $z_{min} = 1.2$, we have⁷

$$k_p \equiv \frac{\sigma_{polyakov}}{(\beta_c - \beta)^{2\nu}} = 3.70(4) \quad (26)$$

which is in impressive and remarkable agreement with the value k_w given in eq.(25).

Let us conclude making the same comparison between Wilson and Polyakov data, without taking into account string corrections.

Since in this case Wilson loops data do not scale and Polyakov data should depend on N_t , we cannot do this comparison at the level of scaling variables k_w and k_p as we did above, but we must examine the data at each value of β and N_t separately. The result is shown in fig.4 and fig.5: there is clearly a gap between the values of σ evaluated with these two different observables.

In order to get a numerical estimate of this gap, we assumed the following rule: consider, both for Wilson loops and for Polyakov line correlations, the first value of the string tension (as z_{min} and R_{min} increase) with a good confidence level of the fit to the pure area law. As discussed above, this means that we must take $R_{min} = 5$ and $z_{min} = 0.8$. With this criterion we obtain:

$$\begin{aligned} &\sigma(N_t = 13, \beta = 0.739, R_{min} = 5)_{wilson} = 0.0338(7) \quad , \\ &\sigma(N_t = 13, \beta = 0.739, z_{min} = 0.8)_{polyakov} = 0.0315(4) \quad , \\ &\text{with a gap } 0.0023(11) \quad ; \\ &\sigma(N_t = 15, \beta = 0.746, R_{min} = 5)_{wilson} = 0.0214(3) \quad , \\ &\sigma(N_t = 15, \beta = 0.746, z_{min} = 1.2)_{polyakov} = 0.0195(3) \quad , \\ &\text{with a gap } 0.0019(6) \quad . \end{aligned}$$

⁷The absolute value of σ does not change within the errors taking any value of $z_{min} \geq 1.0$. Only the error is a function of z_{min} and we choose, of course, the z value corresponding to the maximal confidence level, which is higher than 70%.

Remarkably, both are compatible with a value $\tilde{c} = 1$ for the effective conformal anomaly. Indeed, since these gaps should be due, at least asymptotically, to the term $\frac{\tilde{c}\pi}{6N_t^2}$ of eq.(17), setting $\tilde{c} = 1$, we expect a gap of 0.0031 for $N_t = 13$ and of 0.0023 for $N_t = 15$.

Needless to say that these numbers must be taken with caution, since both the σ_p and σ_w are still moving toward their asymptotic values in the region that we are measuring. Notwithstanding this, they clearly indicate the presence of a gap between the two estimates of σ , and this fact can simply be understood only in the context of an effective string picture of the infrared behaviour of the gauge theories.

Figure Captions

Fig.1) The string tension σ as a function of z_{min} for the fermion, boson and no-string pictures at $\beta = 0.746, N_t = 15$.

Fig.2) Polyakov line correlations as functions of the adimensional ratio $z = 2R/N_t$. Three samples of data are presented: $\beta = 0.746, N_t = 16$, $\beta = 0.742, N_t = 14$ and $\beta = 0.742, N_t = 13$. The first two, which overlap in the figure, correspond to the same physical temperature T . The third one, with error bars, is plotted for comparison.

Fig.3) The interquark potential $V(R)$ defined in eq.(23) as a function of the distance R . The data are taken from the sample at $\beta = 0.746, N_t = 15$, error bars are presented only for $R > 8$. For $R < 8$ errors are smaller than the plotted symbols. The straight line corresponds to the pure area law fit. The dashed line is the fit with the fermionic string correction while the dotted line is the fit with the bosonic string correction.

Fig.4) String tension extracted from the Polyakov line correlations (square) and from Wilson loops (diamonds) using a pure area law, without string corrections, plotted as functions of the short range cutoff R_{min} . The sample of data is at $\beta = 0.746, N_t = 15$. The values of z_{min} for the Polyakov case are converted using the relation $R = z \cdot N_t/2$.

Fig.5) Same as Fig.4, taking into account the fermionic string corrections.

Table Captions

Tab.I Set of measured data: in the third column the corresponding physical temperatures are presented. In the last column we list the samples in which also Wilson loops were measured.

Tab.II Values of string tensions extracted from Wilson loops as functions of R_m for the two set of data: $\beta = 0.739$, $\beta = 0.746$ presented in this paper and for three sets of data of ref. [7]: $\beta = 0.740$, $\beta = 0.745$, $\beta = 0.750$. The string tension is presented in scaled unities in the case of the pure area law fits (IIa) and taking into account fermionic string corrections (IIb). In both tables the sixth line contains the result (k) of the scaling fit and the last line the corresponding reduced χ^2 and confidence levels.

Tab.III Values of string tensions extracted from Polyakov line correlations as functions of z_{min} . The string tension is presented in scaled unities in the case of the pure area law fits (IIIa) and taking into account fermionic string corrections (IIIb). In both tables the last two lines contain the result (k) of the scaling fit and the corresponding reduced χ^2 and confidence levels.
